FERMILAB-TM-2102

Chemical and Radiochemical Background Concentrations of Geologic Materials
Beneath Fermilab

P.M. KESICH, K. VAZIRI, N. GROSSMAN

FERMI NATIONAL ACCELERATOR LABORATORY

FEBRUARY 22, 2000

ABSTRACT

This document consists of a group of tables containing chemical and radiochemical analytical results of samples of geologic materials at Fermi National Accelerator Laboratory. The results are for materials from ground surface to approximately 375 feet below ground surface. The results are from materials obtained from previously undisturbed areas and represent background values. Material for analyses were taken from boreholes drilled as part of the NuMI ground water monitoring network.

The current methodology in use at Fermilab for estimating radionuclide production in soil or rock and migration in the saturated zone to the regulated ground water, is the Concentration Model. Malensek, et al. (Fermilab-TM-1851), proposed this model in 1993 as a new approach over the previously used Single Resident Well Model (Jonckheere, December 1978). EP Note 8 (Cossairt, December 1994), summarized the principal conclusions and made a specific recommendation to the Fermilab Director concerning the application of the results to the future design of targets and absorbers at Fermilab. Subsequently, clarification and modification of aspects of the model were done (Cossairt et al., EP Note 17) and its application for unique conditions addressed (Grossman et al., Fermilab-TM-2103).

One of the parameters of the Concentration Model is the average star density ($\langle S \rangle$) in the geologic material outside of the targeting enclosure. This value is determined from a Monte Carlo computer program for the simulation of hadronic and electromagnetic cascades. Input to the program can be for generic material or can include specific chemical compositions. Part of the output of this program is tables and contour plots of star density for the composition and geometry of the area. In the determination of shielding and operational design, the composition of the formation outside of the production area may be an important factor when calculating residual dose rates.

The chemical composition of soil outside of a beam enclosure has been made for limited cases along with activation products from soil and rock (Fairman, et el. 1970, Awschalom 1971, Borak et el. 1972, Gollon 1978, Cupps 1998). Chemical analyses of Illinois limestones and dolomites have been compiled to present information regarding the various rock formations for use in evaluating the chemical character of these resources by the Illinois State Geological Survey (1957). This report focuses on the background chemical and radiochemical composition of samples of geologic materials from the ground surface to approximately 375 feet below ground surface¹. The materials consist of the consolidated bedrock formations that make up the upper bedrock aquifer and the unconsolidated glacial deposits that confine them. Samples of geologic material were taken from cores that were drilled during the initial ground water monitoring network installation for the NuMI project. Radiochemical analysis was performed at the onsite Activation Analysis Laboratory² and chemical analysis was performed at an offsite vendor, Actlabs-Skyline, Tucson, AZ³. Detailed descriptions of the stratigraphy are documented (Rust 1996, STS 1997 and Earth Tech 1999.) With this information on the background chemical and radiochemical composition of geologic materials, comparisons can be made between dose rates obtained using "standard" geologic material compositions and the actual chemical compositions.

¹ The last sample was taken from 340.5 feet below ground surface, however the borehole extended to 375 feet with a similar lithology from 340 to the bottom of the core.

² Radiochemical analysis was for gammas only. The samples were crushed and transferred to a poly bottle prior to counting. Each sample was then counted for 14,400 seconds at 1.2234 cm on detector Ge(Li)#1. The total gross counts for each sample was measured in the energy range of 20-3050 keV. The background counts were subtracted from the sample counts prior to the activities being calculated. Activities were corrected back to the time of sampling. Water was not driven off of the samples for tritium analysis.

³ Samples were analyzed at research grade using Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES), Instrumental Neutron Activation Analysis (INAA), and Inductively Coupled Plasma Mass Spectroscopy (ICP-MS) technologies.
